### Introduction to the Boston Housing Dataset

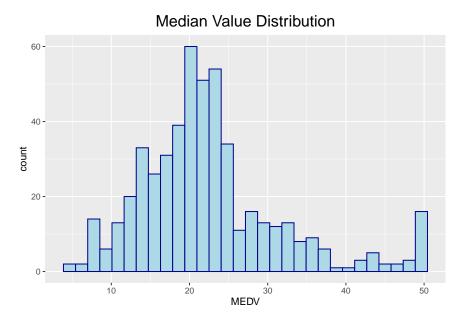

The Boston Housing dataset considers housing values and their associated properties in suburbs of Boston, Massachusetts. The dataset contains 506 observations and 14 attributes. We acquired the dataset from the Machine Learning Database (MLDB), found here. In particular, we are interested in constructing a model through regression techniques to gain insight on housing values. As such, we will use the 13 features to model 'MEDV', the median value of owner occupied homes (in \$1,000s).

The data is displayed as follows.

```

## **Exploratory Data Analysis**

#### **MEDV** Distribution

The histogram demonstrates the values are not uniformly distributed. Rather, they follow a mostly normal distributions, with some outliers at the tail.

#### **Correlation Matrix**

While we produce many correlation values, we are firstly interested in how each attribute correlates to MEDV. This is represented by the bottom row or last column. We can immediately see the binary CHAS attribute does not correlate strongly with MEDV. However, it can be seen that RM (0.7) and LSTAT (-0.74) correlate with MEDV stronger than other attributes. Furthermore, the correlation between RM and LSTAT is -0.61. Since they do not correlate very strongly with one another, we can select both as predictor attributes without too much concern of collinearity for their case. The greatest correlation is between RAD and TAX

of 0.91. Including both of these may raise some concerns regarding the minimal collinearity assumption of linear regression.

#### Example EDA subsection title 3

### Modelling and Regression

MedV takes the value for Y, along 13 feature attributes of the dataset, in the form of  $Y = \beta_0 + \beta_1 x_1 + ... + \beta_n x_n$ .

#### **Multiple Linear Regression**

This is very subject to change. I chose to simply split the data in a 80/20 split. If you think we should consider another split, or more, please do so. Furthermore, this is simply a start, and have yet to articulate everything. Please feel free to make changes.

Naively consider most attributes at onset.

```

```

Some initial insight is that LSTAT and RM indeed were strong predictors. Removing INDUS and AGE, every attribute becomes a significant predictor with the possible exception of B, depending on alpha. Let's consider what happens if we remove RAD, which varies strongly with TAX.

MSE4
# All Output are around 21 YET the ridge produces something like 42046.
# How do we compare these two? Where is the error in my multiple lin regression?
```

Lasso with parameter tuning will give us further insight into parameter selection. This section can/should be expanded/refined.

### Ridge Regression

##

## min 0.678

## 1se 4.357

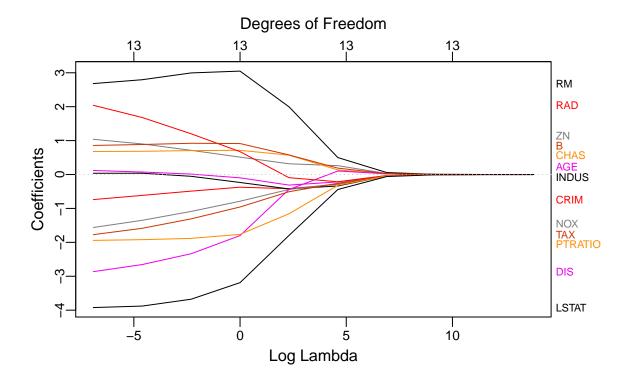

Lambda Index Measure

100

80

Constructing a ridge model.

```
#lambda grid
grid <- 10^seq(6, -3, length=10)
#ridgeModel
ridge.mod <- glmnet(scale(x), y, alpha = 0, lambda = grid, thresh = 1e-2, standardize = TRUE)
plot_glmnet(ridge.mod, xvar = "lambda", label = 13)</pre>
```

Considering a best lambda for the model and hyperparameter tuning.

23.68 3.797

27.10 4.220

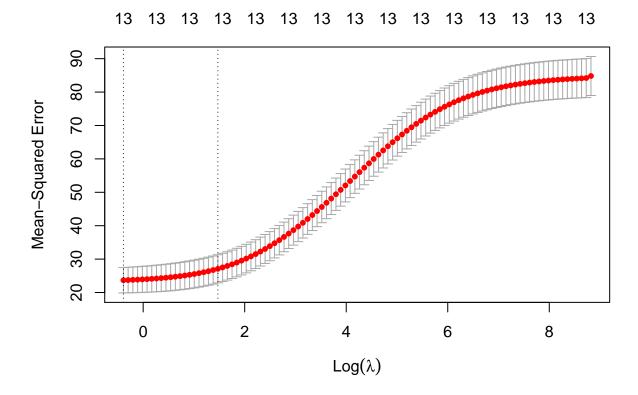

```
cv.out <- cv.glmnet(x, y, alpha=0, nfolds = 10)
cv.out

##
## Call: cv.glmnet(x = x, y = y, nfolds = 10, alpha = 0)
##
## Measure: Mean-Squared Error
##</pre>
```

SE Nonzero

13

13

```
best.lambda <- cv.out$lambda.min
best.lambda</pre>
```

#### ## [1] 0.6777654

Considering coefficients for ridge.

```
ridge.final <- glmnet(scale(x), y, alpha = 0, lambda = best.lambda, thresh=1e-2, standardsize = TRUE)
predict(ridge.final, type="coefficients", s=best.lambda)</pre>
```

```

## TAX -0.7510226 ## PTRATIO -1.8099040 ## B 0.8974522 ## LSTAT -2.8927874

Considering MSE and RMSE for ridge using all coefficients.

## [1] 42046.5

## [1] 205.0524

## Lasso Regression

#### K-Fold Cross Validation

A simple quick table for us to store into for now:

	MSE	RMSE
Multiple	0	0
Multiple 2	0	0
Ridge	0	0
Lasso	0	0
